Abstract

Vigilance behavior may directly affect fitness of prey animals, and understanding factors influencing vigilance may provide important insight into predator-prey interactions. We used 40,540 pictures taken with camera traps in August 2011 and 2012 to evaluate factors influencing individual vigilance behavior of white-tailed deer (Odocoileus virginianus) while foraging at baited sites. We used binary logistic regression to determine if individual vigilance was affected by age, sex, and group size. Additionally, we evaluated whether the time of the day, moon phase, and presence of other non-predator wildlife species impacted individual vigilance. Juveniles were 11% less vigilant at baited sites than adults. Females were 46% more vigilant when fawns were present. Males and females spent more time feeding as group size increased, but with each addition of 1 individual to a group, males increased feeding time by nearly double that of females. Individual vigilance fluctuated with time of day and with moon phase but generally was least during diurnal and moonlit nocturnal hours, indicating deer have the ability to adjust vigilance behavior to changing predation risk associated with varying light intensity. White-tailed deer increased individual vigilance when other non-predator wildlife were present. Our data indicate that differential effects of environmental and social constraints on vigilance behavior between sexes may encourage sexual segregation in white-tailed deer.

Introduction

Non-consumptive predation effects can impact interactions of prey species with their environment and may negatively affect fitness [1]. High predation risk may reduce fitness by simplifying an animal’s decision making rules, which potentially hinders optimal use of resources, particularly when foraging areas are separated from escape cover [2]. Therefore, predation risk may have an impact on prey behaviors and subsequently affect fitness of the population [3]. Behaviors that potentially reduce fitness may include reduced feeding durations [4–5], decreases in diel activity [6], changes in group size [7,8], changes in habitat use [9–12], and increases in vigilance while foraging [13].

During feeding, vigilance behavior comes at a cost if intake rates are decreased [14–16]. However, ungulates generally accept the cost of vigilance during foraging because the cost of decreasing intake is a lower proximal threat to the individual fitness than increased predation risk [7]. Therefore, individual vigilance should be positively correlated to perceived predation risk [17]. Furthermore, individuals may increase group sizes to decrease individual vigilance during foraging without increasing predation risk [8].

The predation risk hypothesis predicts that larger male ungulates are less vulnerable to predation than females and young, and males select areas with higher quality resources and greater predation risk, whereas females select lower quality patches where predation risk is less [18,19]. Similarly, the predation risk allocation hypothesis predicts animals will respond to pulses in predation risk by allocating more time to anti-predator behaviors, and animals will respond quickly to fluctuations in risk [20,21]. Both hypotheses may explain sexual segregation of sexually dimorphic ungulates [18,19]. Because white-tailed deer (Odocoileus virginianus) are sexually dimorphic, males and females should perceive different predation risks and diverge in anti-predator behavior. Both hypotheses may explain sexual segregation of sexually dimorphic ungulates [18,19]. Because white-tailed deer (Odocoileus virginianus) are sexually dimorphic, males and females should perceive different predation risks and diverge in anti-predator behavior. Both hypotheses may explain sexual segregation of sexually dimorphic ungulates [18,19]. Because white-tailed deer (Odocoileus virginianus) are sexually dimorphic, males and females should perceive different predation risks and diverge in anti-predator behavior.
White-Tailed Deer Vigilance

would be less vigilant than females because of larger body size, juveniles would be less vigilant than adults because of inexperience, both sexes would decrease individual vigilance with increasing group size, and vigilance would be greatest during the brightest times of the day and night (i.e., full moon), when their predators presumably had the best eyesight conditions. Furthermore, we hypothesized the presence of other non-predator wildlife species would decrease vigilance behavior by increasing the interspecific group size.

Ethics Statement
This research was performed in accordance with the United States Department of Defense and Fort Bragg Military Installation research permit. No animals were handled in this study. The funders designed the sampling scheme and camera trap positions based on proper techniques for white-tailed deer population surveys as indicated by previous literature; however, the funders had no role in data collection and analysis, decision to publish, or preparation of the manuscript.

Materials and Methods

Site Description
We conducted our study on Fort Bragg Military Installation (Fort Bragg), located (35°7′ N, 79°9′ W) within the Sandhills physiographic region in the lower coastal plain of North Carolina, USA. Forests were managed with growing-season prescribed fire on a 3-yr fire-return interval. Upland forests were dominated by longleaf pine (Pinus palustris) with wiregrass (Aristida beyrichiana) understories [30]. Potential predators of deer included coyotes (Canis latrans), bobcats (Lynx rufus), and humans. Deer were hunted in accordance with state game regulations from the first Saturday in September to 1 January each year. The large area and fairly homogeneous land management across Fort Bragg allowed us to uniquely isolate the effects of social and environmental variability on vigilance behavior.

Data Collection
In August of 2011 and 2012, we established 100 baited sites (i.e., 50 sites established August 1 and 50 sites established August 8). We chose to conduct our study in August because the effects of hunting on vigilance were minimized and we could monitor pre-harvest population density and fawn recruitment as described in Jacobson et al. [31]. We set sites in a grid design across Fort Bragg so there was 1 camera per 500ha (i.e., 50,000ha ÷ 100 sites), which is much larger than the reported summer home range (40–90ha) of white-tailed deer [32]. We pre-baited for 14 days and then activated cameras to take pictures for 14 days and as frequently as every 3 minutes [31]. Cameras were triggered by motion and heat and were equipped with infrared flash to reduce startling deer during nocturnal hours. After the 14 days of camera trapping, we collected all pictures and tallied the number, sex, and age of deer, their vigilance level, the time and date of the picture (rounded to the nearest hour), presence of other wildlife species, and the moon phase (New, First quarter, Full, Third quarter, as described in Rockhill et al. [33]). We considered a deer to be in a feeding posture if its head was below its stomach line (non-vigilant) and classified it as non-feeding posture when its head was above the stomach line. We determined sex based on the presence or absence of antlers; if the head was not visible the deer was considered non-feeding posture (feeding posture = 1 and non-feeding posture = 0) being the possible outcomes. Age (Adult = 1 and Juvenile = 0), sex (Male = 1 and Female = 0), group size, time, presence or absence of other wildlife species (Absent = 1 and Presence = 0), and moon phase were set as independent variables in the model; we included all interactions between sex and other independent variables and the moon phase × time of day interaction. We set alpha to 0.05. Also, we reported the time spent non-vigilant (i.e., pictures in feeding posture ÷ total number of pictures). Because some of the time spent in non-feeding postures could be spent handling forages (or otherwise non-vigilant; [34]), our assessment of time spent foraging is a conservative estimate of actual foraging behavior.

Results
We collected 40,540 photographs of deer. We discarded 234 pictures because of inability to determine sex, age class, or posture. Pictures were relatively homogeneously distributed among cameras with only one camera site failing to receive any deer use. Less than 1000 pictures were confined to any single camera site per year, which minimized the weight of unique behavior at any camera site throughout the study. We recorded 24,934 pictures of females, 15,372 of males, 17,567 pictures with a group size of 1, 14,285 in group sizes of 2, 6, 194 in groups of 3, and the remainder in group sizes of 4 or larger (largest group = 7). Males were 20% less vigilant than females while foraging at baited sites (Table 1). Deer were less vigilant in the post-meridiem (Table 1, Figure 1) and less vigilant during brighter moon phases (Table 1, Figure 2). Both males and females spent more time feeding while at baited sites as group size increased, but with each addition of 1 individual to a group, males increased feeding time by nearly double that of females (7% per individual in females and 15% per individual in males) (Table 1, Figure 3). Males continued to increase feeding time up to group sizes of 5, but females did not increase feeding time in groups larger than 4 (Table 1, Figure 3). Females were 46% more vigilant when fawns were present (P < 0.001), and juveniles were less vigilant at baited sites than adults, averaging 11% less vigilant behavior (Table 1). Also, males and females were 10% more vigilant when other wildlife species were present (Table 1).

Discussion
Our results support the premise that sexual segregation of white-tailed deer may be based on differences in risk perception between sexes [18,21,22,33]. Males were less vigilant at baited sites, likely because they perceive lower predation risk by natural predators due to their larger body size compared to females [18]. Variation in risk perception potentially changes feeding durations [4,5], daily movement [6], and group sizes [8] and these changes may contribute to sexual segregation without requiring resource partitioning or competitive exclusion of one sex over the other [36].

Deer were less vigilant during brighter periods, likely because they were better able to see predators. However, this is inconsistent with other prey species that secondarily use eyesight to detect predators [28]. Though deer eyesight is fairly poor in comparison...
to other senses (e.g., smell and hearing; [37]), eyesight is important in determining the intent of an approaching predator [38]. Whereas, olfactory cues may be important for establishing overall predation risk [39], we assumed scent deposition from predators was not correlated with light intensity. Therefore, diurnal and moonlit nocturnal hours likely allow a greater visual capability with additional information about predation risk, which allows deer to be less vigilant while foraging.

Time spent feeding increased as group size increased, likely because individuals were able to spend less time scanning for predators and more time foraging without increasing predation risk per individual [40]. The influence of group size on individual vigilance has been well-documented [13,40,41] and grouping behavior clearly affects fitness [42]. However, the magnitude of change was different between males and females, contrasting other studies that reported either little effect of group size on individual vigilance of males or less difference in magnitude between sexes as group size increases [43–46]. In sexually dimorphic cervids, sexual segregation is most pronounced during non-mating seasons when the sexes are in large groups [47]. Therefore, the difference in vigilance behavior between the sexes we observed as a result of group size coupled with other social dynamic constraints could be a causal mechanism for the ubiquitous sexual segregation of dimorphic ruminants outside the mating season [47–48].

Greater vigilance behavior by females may confound the nutritional demands of lactation (May-August at Fort Bragg) by requiring greater time spent foraging to support the already heightened intake requirements. Because lactation is the most nutritionally demanding physiological condition in deer [49] and requires an increased forage intake rate from that of other physiological conditions [50], vigilance behavior may come at a greater cost to females during lactation. Toigo [51] reported lactating female French Alpine ibex (Capra ibex ibex) had greater vigilance than their non-lactating conspecifics and offset the additional time of vigilance behavior by decreasing the time resting between foraging bouts. In areas of high predation risk,
Figure 2. Influence of moon phase and time of day on time spent non-vigilant by white-tailed deer while at baited sites at Fort Bragg Military Installation, North Carolina, USA, August 2011 and 2012. Time spent feeding was greater during moonlit nocturnal hours (P<0.001).

increasing movement rates could lead to a paradoxical situation whereby increased movement predisposes an individual to predation if it is trying to offset by moving more often between feeding bouts; in such cases, predation risk could result in a significant reduction in fitness. Increased vigilance during lactation may result in increased time spent searching for food [12,20] and decreased use of high-quality food patches [51]. Concomitantly, increasing the time spent foraging and searching for foods may increase risk of predator-prey interactions, which may require increased vigilance [17]. Eventually, the time budget may not allow lactating females to acquire enough resources to support lactation, which could lead to neonate starvation by abandonment coupled with substantially reduced resources to support lactation, which could lead to neonate interactions, which may require increased vigilance [17]. Conclusions

Vigilance behavior plays a major role in the acquisition of resources and predator avoidance. Our data indicate environmental and social factors influence individual vigilance. Furthermore, sexual segregation may be encouraged by differential effects of environmental and social factors between sexes. Further investigation of the influence of vigilance behavior on sexual segregation is warranted.
